Abstract

Attention control regulates efficient processing of goal-relevant information by suppressing interference from irrelevant competing inputs while also flexibly allocating attention across relevant inputs according to task demands. Research has established that developing attention control skills promote effective learning by minimizing distractions from task-irrelevant competing information. Additional research also suggests that competing contextual information can provide meaningful input for learning and should not always be ignored. Instead, attending to competing information that is relevant to task goals can facilitate and broaden the scope of children's learning. We review this past research examining effects of attending to task-relevant and task-irrelevant competing information on learning outcomes, focusing on relations between visual attention and learning in childhood. We then present a synthesis argument that complex interactions across learning goals, the contexts of learning environments and tasks, and developing attention control mechanisms will determine whether attending to competing information helps or hinders learning.

Keywords: attention control, executive attention, attention flexibility, context, learning

1
2
3 Visually attending to competing or distracting information is often viewed as a processing
4 failure. While there are scenarios where distraction hinders learning, the complexity generated by
5 competing information may also offer rich input for learning. Here we argue that whether
6 competing information hinders or helps learning likely depends on multiple factors, including the
7 learning context and the developmental state of attention control and learning and memory
8 systems. Although we will primarily focus on formal learning environments in which learning
9 goals are more clearly defined (e.g., controlled laboratory tasks, classrooms), we will also consider
10 how attending to competing information may influence learning in informal contexts without a
11 defined learning goal. We focus this review as much as possible on literature specific to early and
12 middle childhood (i.e., 3-10 years of age) to align the discussion with broader issues in education
13 and learning spaces.

28 Attention control is often equated with executive attention, the ability to select goal-
29 relevant information while suppressing irrelevant competing information (Burgoyne & Engle,
30 2020). Yet daily adaptive behavior requires focusing on high-level task goals while also remaining
31 sensitive to novel or changing contexts (Chevalier, 2015; Dajani & Uddin 2015). For example, one
32 might have the goal of making a jelly sandwich and must execute a series of subtasks in sequential
33 order to successfully complete this goal (Desrochers et al., 2016). Within each sub-task, one must
34 be sensitive to detailed contextual visual information. If someone has moved the jar of jelly from
35 its habitual cupboard location, one must engage attention control to arbitrate among possible
36 locations the jar could be found while also inhibiting attention to irrelevant objects and locations,
37 all while maintaining the high-level goal of making the sandwich. Thus, attention control
38 comprises both executive attention as well as the ability to flexibly allocate attention in service of
39 a broader goal (Braem & Egner, 2018; Diamond, 2013). We will first describe the development of

2
3 these attention control mechanisms and review research demonstrating that attending to irrelevant
4 or extraneous competing information can hinder children's learning in childhood. Next, we will
5 describe evidence indicating that contextual information can provide meaningful input for learning
6 and attending to this relevant competing input can facilitate and broaden the scope of learning.
7
8 Finally, we will synthesize these literatures by reviewing data that suggest that multiple factors
9 may define whether attending to competing information is a useful part of the learning process.
10
11 Rather than assuming that all competing information will hinder learning, we argue that the
12 learning goals and context, paired with developing attention control and memory processes,
13 influence children's learning in the presence of competing information.

26 ***Developing Attention Control***

27
28 We live in complex, dynamic environments that contain multiple sources of competing
29 sensory inputs. To avoid information overload, we rely on attention to select a subset of these
30 inputs and enhance processing of the selected information (Luck & Vecera, 2002; Oakes & Amso,
31 2018). Learning environments typically contain a wide range of multisensory information and past
32 research has shown that the presence of redundant audiovisual cues may promote children's
33 learning to a greater extent than visual or auditory cues alone (Broadbent et al., 2018, 2019).
34
35 However, while researchers have begun to examine the development of multisensory attention
36 control mechanisms (Matusz et al., 2015, 2018, 2019; Turoman et al., 2021), most research linking
37 developing attention control to learning outcomes has focused on children's attention to competing
38 visual inputs. We will therefore primarily focus on visual attention mechanisms that allow for
39 selection of relevant information and suppression of competing information in the visual
40 environment. This concurrent selection and suppression results in sharpened visual processing of

3 objects and locations and provides input for subsequent perception, action, and learning and
4 memory systems (Amso & Scerif, 2015; Carrasco, 2011, 2014; Markant et al., 2015; Zhang et al.,
5
6 2011).

7
8
9
10 Posner and Petersen's (Petersen & Posner 2012; Posner & Petersen, 1990) seminal model
11 defined three separate but interrelated attention processes, including alerting, orienting, and
12 executive attention. Alerting maintains a state of arousal and readiness to respond to external
13 information. Orienting involves shifting attention to select information in the environment, which
14 can occur either with a concurrent eye movement (overtly) or independent of an eye movement
15 (covertly). Finally, executive attention processes resolve conflict between competing sources of
16 input in order to efficiently select goal-relevant information (Fan et al., 2003; Posner & Rothbart,
17 2009). Executive attention is one component of a broader set of executive functions (e.g.,
18 Diamond, 2013), with executive attention mechanisms specifically supporting top-down guidance
19 of attention and inhibition of task-irrelevant information (e.g., Rothbart et al., 2007; Tiego et al.,
20 2020).

Researchers have relied on a broad range of tasks to examine these attention processes. The development of attention orienting has been studied extensively using visual search tasks, in which a single target item appears among a varying number of competing distractors (Treisman & Gelade, 1980). When the target and distractors share multiple features there is increased competition across stimuli in the search array. In this case, increasing the number of distractors slows search times, reflecting the increased effort associated with selecting the target from among multiple competing distractors (e.g., Treisman & Gelade, 1980). Studies using visual search tasks have demonstrated that target selection becomes increasingly accurate and efficient between one

1
2
3 and ten years of age (Donnelly et al., 2007; Gerhardstein & Rovee-Collier, 2002; Scerif et al.,
4
5 2004; Trick & Enns, 1998).
6

7
8 Researchers have examined the development of executive attention using tasks that require
9
10 inhibiting competing or conflicting information for effective task performance. Early foundations
11
12 of executive attention can be measured using tasks that require control over eye movements. For
13
14 example, in the antisaccade task individuals respond by looking away from a visual cue, requiring
15
16 them to inhibit an initial tendency to automatically fixate the cue. Four-month-old infants can
17
18 inhibit orienting to a visual cue (Johnson, 1995), and by 12- to-18 months of age toddlers can
19
20 additionally orient to the opposite, noncued location (Scerif et al., 2005). Researchers have used a
21
22 range of additional tasks that require inhibiting dominant responses to respond to arbitrary rules
23
24 or conflicting information (e.g., Simon Says, Tower, Day-Night Stroop) to demonstrate rapid
25
26 improvement in executive attention skills between 3 and 5 years of age (see Garon et al. 2008 for
27
28 review). These developing executive attention skills have also been observed in studies using the
29
30 Flanker task (Eriksen & Eriksen 1974) and Attention Network Task (Fan et al., 2002), in which
31
32 participants indicate the directionality of a central arrow while ignoring surrounding arrows.
33
34 During some trials the competing arrows point in the same direction as the target, but during other
35
36 trials they point in the opposite direction, requiring increased executive attention to resolve the
37
38 competition with the target. Children show improved performance on this task from 4 to 6 years
39
40 of age (e.g., Rueda et al., 2004; 2005) but also continue to show increasingly efficient executive
41
42 attention skills into middle childhood, especially between 5 and 8 years of age (see Best et al.,
43
44 2009 for review). Studies using the antisaccade and Flanker task have also shown that the ability
45
46 to engage executive attention continues to develop into early adolescence (Hwang et al., 2010;
47
48 Luna, et al., 2004; Waszak et al., 2010). For example, in a study examining the development of
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 attention orienting and executive attention skills from 6 to 89 years of age, children's orienting
4 skills reached adult levels by age 10 but 15-year-old adolescents continued to show poorer
5 executive attention performance (Waszak et al., 2010). Thus, while children show significant
6 improvements in executive attention in early childhood these skills continue to develop gradually
7 through childhood and early adolescence. These age-related changes in executive attention are a
8 core component of developing attention control as they allow for increased focus on task-relevant
9 information and reduced interference from competing, task-irrelevant information.
10
11
12
13
14
15
16
17
18

19 Attention control also requires an ability to flexibly shift attention to new information when
20 task demands change. This flexibility reflects the integration of multiple processes as individuals
21 must detect changes in task contexts, disengage from currently selected targets, and shift attention
22 to information that is relevant to new task goals (Dajani & Uddin, 2015). Researchers have studied
23 the development of attention flexibility using tasks in which stimulus features that were initially
24 irrelevant become relevant for successful task performance (see Hanania & Smith 2010 for
25 review). For example, in the Dimensional Change Card Sort (DCCS) task, participants sort cards
26 based on a single feature (e.g., shape), while ignoring a second feature (e.g., color). The rule is
27 then switched and participants are instructed to sort cards based on the previously ignored feature.
28 Three-year-old children typically have difficulty sorting based on a previously ignored feature, but
29 by 5 years of age children successfully sort based on the new rule (e.g., Brooks et al., 2003; Frye
30 et al., 1995; Kirkham et al., 2003; Perner & Lang, 2002; Towse et al., 2000; Zelazo et al., 1996).
31 Compared to adults, young children spend more time looking at the irrelevant feature (Chevalier
32 et al. 2010) and children show enhanced performance when the task design facilitates focusing on
33 only the relevant information (Bohlmann & Fenson, 2005; Brace et al., 2006; Diamond et al., 2005;
34 Kirkham et al., 2003; Kloo & Perner, 2005; Towse et al., 2000). These results suggest that

1
2
3 successful performance on this task reflects improvements in the ability to flexibly shift attention
4 across relevant stimulus features. Although children typically show successful performance on the
5 DCCS by age 5, studies using more complex tasks have shown that attention flexibility continues
6 to develop after this age (e.g., Amso et al., 2014, 2019; Dick, 2014). For example, during the
7 modified Flexible Item Selection Task (e.g., Blair & Razza 2007; Jacques & Zelazo 2001),
8 participants select two objects from a larger array based on a single matching feature (e.g., color).
9 On subsequent trials participants are asked to select new object pairs that match based on a
10 different feature (e.g., shape). Children showed improvements in their ability to flexibly shift
11 across features during this more complex task from 6 to 8 years of age, and performance reached
12 adult levels by 10 years of age (Dick, 2014). This improving flexibility over childhood may reflect
13 qualitative changes in children's use of strategies (Chevalier, 2015) as well as increased working
14 memory capacity and reduced interference from irrelevant information (Cragg & Chevalier, 2012).

28
29
30

31 The DCCS requires shifting attention across multiple features within a single stimulus.
32 Children also develop increasing control over their ability to flexibly allocate attention across
33 multiple stimuli or locations. Previous work using a range of tasks (e.g., flanker, visual crowding,
34 multiple object tracking) has shown that younger children allocate attention broadly but can focus
35 attention more narrowly with age (Bondarko & Semenov, 2005; Enns & Girgus, 1985; Jeon et al.,
36 2010; Pasto & Burack, 1997; Wolf & Pfeiffer, 2014). For example, Pasto & Burack (1997)
37 examined 4-, 5-, 7-, and 9-year-old children and adults' ability to rapidly respond to targets while
38 ignoring distractors that appeared at varying distances (< 1 vs. 5.7 degrees) from the target.
39 Compared to when distractors were absent, 4-year-old children responded more slowly when any
40 distractors were present, regardless of their distance from the target. However, their filtering of
41 more distant distractors improved when a visual cue limited attention to the space around the target.

52
53
54
55
56
57
58
59
60

1
2
3 Older children were slower only when distractors were located close to the target and adults
4 showed similar responses regardless of whether distractors were present or absent (Pasto &
5 Burack, 1997). These results suggest that young children distribute attention broadly and have
6 difficulty independently scaling attention to narrowly focus on a target location. Enns and Girgus
7 (1985) also examined 8- and 10-year-old children and adults' ability to rapidly classify stimuli by
8 either selectively focusing on a single feature or attending to multiple features. All participants
9 responded more slowly when selectively attending to stimuli that were located close together or
10 when attending to multiple features that were spaced far apart. However, the youngest children
11 showed the largest response time costs in both of these cases, suggesting that they had increased
12 difficulty scaling their attention as task demands changed (Enns & Girgus, 1985). Overall, these
13 results demonstrate that children distribute attention more broadly in early childhood and develop
14 increasing control over the ability to flexibly scale attention based on changing task demands.

30
31 In sum, the development of attention control includes improvements in executive attention
32 skills that support children's ability to resolve conflict across competing inputs and efficiently
33 select goal-relevant information. Children show significant improvements in these executive
34 attention skills between 3 and 5 years of age, but these skills continue to become more refined
35 through middle childhood and into early adolescence. However, developing attention control is
36 also characterized by increased flexibility in attention allocation. Children become better able to
37 shift attention across multiple relevant inputs or to newly relevant information during early and
38 middle childhood, with the most robust improvements occurring by 10 years of age. Although
39 children also show dramatic improvements in their ability to narrowly focus on task-relevant
40 targets in early childhood, the ability to flexibly scale attention either broadly across multiple
41 stimuli or more narrowly based on task demands continues to develop into middle childhood. The

10 ***Attending to Task-Irrelevant Competing Information Hinders Learning***

11
12 Researchers studying attention and learning typically emphasize the importance of
13 attention orienting and executive attention for learning. Many studies have demonstrated that
14 improvements in children's ability to efficiently select task-relevant stimuli and ignore task-
15 irrelevant distractors promotes enhanced learning and memory for the attended information
16 (Blanco & Sloutsky, 2019; Deng & Sloutsky, 2016; Hagen & Hale, 1973; Markant & Amso, 2013,
17 2014, 2016; Plebanek & Sloutsky, 2017). For example, in an early incidental learning paradigm,
18 Hagen and colleagues (Hagen & Hale, 1973) showed 7-13- year-old children cards containing a
19 target image (e.g., animal) and a second competing non-target image (e.g., household object).
20 Participants were instructed to remember the location of the target image and researchers later
21 assessed their memory for the target location and their incidental learning of the pairing between
22 the target and nontarget images. All children showed better memory for target locations without
23 competing images present and the oldest children showed poorer incidental learning of target-
24 nontarget pairs, suggesting increasing selective focus on targets with age (Hagen & Hale, 1973).

42 The presence of competing visual or auditory information can also hinder children's
43 learning in academic or classroom contexts. Individual differences in developing selective
44 attention skills predicted classroom learning efficacy among kindergarten students (Erickson et al.,
45 2015) and relates to academic performance more broadly across development (Stevens & Bavelier,
46 2012). Fisher et al. (2014) compared kindergarten students' learning of science lessons that were
47 taught in classrooms without visual displays versus classrooms that were richly decorated with
48

51
52
53
54
55
56
57
58
59
60

1
2
3 multiple sources of potential visual distraction (e.g., science posters, maps, artwork). During the
4 lessons, researchers observed the children's attention to the instructor, visual displays, and other
5 aspects of the environment. Children who experienced the richly decorated classroom showed
6 reduced engagement with the science lessons, spent more time looking at the visual displays, and
7 demonstrated poorer learning of the lesson content (Fisher et al., 2014). Eight- to twelve-year-old
8 children also showed poorer spatial attention and memory performance when they were tested in
9 a richly decorated vs. a sparsely decorated space (Rodrigues & Pandeirada, 2018). These effects
10 also extend beyond classroom environments to specific learning materials. Kaminski & Sloutsky
11 (2013) presented kindergarten, first- and second-grade students with bar graphs that contained
12 perceptual features that were irrelevant to the mathematical concept conveyed by the graph. The
13 presence of this irrelevant information interfered with children's ability to accurately read the
14 graphs, especially at younger ages (Kaminski & Sloutsky, 2013). Eng et al. (2020) similarly
15 examined effects of extraneous story book illustrations on first- and second-grade students'
16 attention and reading comprehension. Children viewed a book in which a portion contained
17 standard illustrations while the remainder was presented with extraneous illustrations removed.
18 Children were less likely to look away from the text and showed improved story comprehension
19 when the extraneous illustrations were removed.

32
33
34
35
36
37
38
39
40
41

42 Some of these studies have further found that these effects are exacerbated for children
43 who are prone to attend to competing visual or auditory information due to immature or atypical
44 attention skills. Massonnie et al. (2019) used idea generation tasks to assess the effects of
45 moderate-level classroom noise on 5-8 and 8-11-year-old children's creativity. The researchers
46 also assessed children's performance on a Stroop executive attention task that required inhibiting
47 conflicting information to correctly identify task-relevant targets, with more mature executive
48
49
50
51

53
54
55
56
57
58
59
60

1
2
3 attention characterized by faster target responses despite the presence of conflicting information.
4
5 Older children's creative responses were not affected by the presence of classroom noise. In
6
7 contrast, the impact of classroom noise on the younger children's creativity was influenced by
8
9 individual differences in their attention skills. Specifically, those with more mature executive
10
11 attention showed similar levels of creativity regardless of classroom noise. However, those who
12
13 showed poorer executive attention performance were less creative in the presence of classroom
14
15 noise, suggesting that they may be more susceptible to distraction during classroom activities
16
17 (Massonnie et al., 2019). Similar effects have been observed using video stimuli designed to
18
19 simulate classroom environments. Five- to thirteen-year-old typically developing children and
20
21 children with autism spectrum disorders (ASD) viewed instructional videos that appeared either
22
23 without peripheral visual information or with multiple images appearing in the background
24
25 (Hanley et al., 2017). All children spent more time looking at the background images when they
26
27 were present but this effect was enhanced among children with ASD, with more severe autistic
28
29 symptoms and poorer sustained attention skills predicting increased looking to the competing
30
31 peripheral information. Overall, these studies suggest that extraneous visual or auditory
32
33 information in classroom settings can negatively impact learning, particularly for children with
34
35 poorer attention skills who may have more difficulty inhibiting attention to this competing
36
37 information.

41
42
43
44
45
46

47 *The Value of Considering Learning Contexts*

48

49 Researchers often ensure that laboratory-based experiments examining attention and
50
51 learning include clearly defined tasks with distinct goal-relevant targets and competing
52
53 information (i.e., distractors) that is irrelevant for successful task completion. In these "context-
54
55
56
57
58
59
60

1
2
3 independent” tasks, efficient performance requires a selective focus on the target and suppression
4 of the competing distractors (Ackerman, 1990). Attending to competing information in this context
5 would be expected to hinder learning of the target. For example, a series of studies using a spatial
6 cueing task demonstrated that engaging visual selective attention to select a target while inhibiting
7 attention to a competing spatial location supported enhanced memory for the attended target.
8 During the spatial cueing task participants focused on a central location while a salient cue
9 appeared in the periphery. After a brief delay a target object appeared in either the same cued
10 location or in the opposite, noncued location. A short cue-target delay (< 250 ms) facilitates
11 orienting responses to targets appearing in the cued location, whereas longer delays elicit an
12 inhibition of return (IOR) response in which orienting to the cued location is suppressed and
13 participants are biased to select targets appearing in the noncued location (Posner, 1980; Posner
14 1985). In a subsequent memory task, infants, children and adults consistently showed enhanced
15 recognition memory when they engaged this IOR response to select the target while inhibiting
16 orienting to the previously cued location (Markant & Amso, 2013, 2014; Markant et al., 2015).
17 Thus, in this context-independent task, the ability to efficiently suppress competing information
18 during target selection was related to enhanced learning about the selected information.
19
20
21

34
35
36
37
38
39

40 However, one can envision a learning context where competing information is not arbitrary
41 but instead provides meaningful input for learning. For example, the spatial context in which a
42 child typically plays with a toy (e.g., their playroom) may provide cues that facilitate their attention
43 to and learning about the toy. A rich adult literature has extensively considered how these scene
44 semantics influence both attention and learning. A classic example used in Loftus & Mackworth
45 (1978) is a line drawing of a farmyard with objects strewn about including a tractor on one trial
46 and an octopus in the same location on another trial. Observers attended more to the octopus, even
47
48
49
50

54
55
56
57
58
59
60

1
2
3 when in the same location, as it was incongruent with the scene context. This top-down mechanism
4 involves goal-directed attention control (Hayhoe et al., 2003; Jovancevic et al., 2006) paired with
5 prior learning of scene content (Neider & Zelinsky, 2006; Henderson et al., 2009; Tatler et al.,
6 2010). Wu, Wick, and Pomplun (2014) argue that scene semantic content or contextual
7 information is processed in a memory-based manner and indeed this memory guides visual
8 attention (memory-guided attention). In our view, the content of competing information must be
9 considered in any discussion of attention control for learning, since children often bring prior
10 knowledge to real-world scenes and learning environments.
11
12
13
14
15
16
17
18
19
20
21

22 Indeed, research using learning and memory paradigms has confirmed that the presence of
23 competing contextual information that is task relevant can facilitate learning. For example, when
24 a target is learned in relation to a repeated background context, the competing nontarget
25 information may be encoded broadly as target relevant. When presented later in isolation in a
26 subsequent memory task, the target may not be recognized as familiar because it is no longer
27 presented paired with the previous context. Consistent with this idea, infants', children's, and
28 adults' memory performance can be disrupted by changes to contextual information (e.g.,
29 background colors, scene information) that was reliably present during target encoding (e.g., Edgin
30 et al., 2014; Hayes et al., 2007; Hayne et al., 2000; Jones et al., 2011). Edgin et al. (2014) found
31 non-linear changes in the extent to which changing contextual information disrupted memory
32 encoding from 3 to 16-years of age. Participants encoded target objects that were learned in the
33 context of naturalistic scenes (e.g., a table within a dining room). During a subsequent recognition
34 memory test, the target objects appeared either within the same scene context or on a white
35 background. Although children younger than 4.5 years and older than 13 years of age both had
36 more difficulty recognizing target objects when the context was changed, the authors attributed

60

1
2
3 younger and older children's use of contextual information during encoding to different underlying
4 mechanisms. Specifically, they argued that the youngest children encoded the targets and their
5 context into a single unified representation, whereas the oldest children's increased reliance on
6 contextual information reflected an increased ability to remember scene details and link them to
7 the target. This pattern of results suggests that developing memory skills allow children to
8 increasingly recognize target-context associations and flexibly use relevant contextual information
9 during learning (Edgin et al., 2014).
10
11
12
13
14
15
16
17
18

19 These findings suggest that more work needs to be done to understand the mechanisms that
20 contribute to poorer memory for targets in the presence of competing contextual information, as
21 well as those that boost learning when relevant contextual information is available. Indeed, unlike
22 experiments in which "task-relevant" targets and "task-irrelevant" distractors are clearly defined,
23 the competing information that is present in young children's daily learning tasks often cannot be
24 easily classified as goal-irrelevant noise. It is in these "context-interactive" situations that attending
25 to competing information that is meaningful to ongoing tasks can facilitate task performance
26 (Ackerman, 1990). While most work has emphasized the importance of executive attention for
27 effective learning, additional research has demonstrated that young children's broader distribution
28 of attention may facilitate learning from both target and competing non-target information. In their
29 incidental learning paradigm described earlier, Hagen and Hale (1973) found that younger children
30 showed enhanced incidental learning of the target/non-target image pairs, suggesting that their
31 broader distribution of attention promoted learning of both target and competing information. In
32 more recent work, Deng and Sloutsky (2015, 2016) found age-related changes in children's
33 processing of non-target information during category learning tasks. In these studies, 4- and 6-7-
34 year-old children and adults viewed items from two categories of novel alien creatures consisting

2
3 of seven features (i.e., head, body, hands, feet, antennae, tail, body mark). One of these features
4 (the “deterministic feature”) could be used to reliably distinguish between the two categories. The
5 remaining features (the “probabilistic features”) frequently predicted category membership but
6 also sometimes appeared on items from the opposite category. As a result, participants could
7 categorize items based on a single deterministic feature or multiple probabilistic features. Older
8 children and adults relied on the deterministic feature for categorization and showed better memory
9 for this target feature, unless attention was intentionally directed to the probabilistic features. In
10 contrast, 4-year-old children showed similar memory for deterministic and probabilistic features,
11 regardless of their categorization strategy, suggesting that they attended to and learned from a
12 broader range of information (e.g., Deng & Sloutsky, 2016). Compared to adults, 4-5-year-old
13 children also showed enhanced memory for irrelevant features during a visual search task and were
14 more likely to notice changes that occurred on irrelevant, uncued objects (Plebanek & Sloutsky,
15 2017). These findings suggest that young children’s broader distribution of attention promotes
16 learning from both task-relevant targets and competing, non-target information.

17
18
19 This broader distribution of attention can be especially beneficial when the competing
20 information is meaningful to an ongoing learning task. In a study similar to those described above,
21 4-year-old children and adults completed a learning task in which two categories of novel alien
22 creatures could be defined based on a single deterministic feature or multiple probabilistic features
23 (Blanco & Sloutsky, 2019). Each exemplar also contained a feature that was initially irrelevant for
24 categorization, but then became the defining feature midway through the task. Adults showed a
25 larger performance cost after this shift, suggesting that they focused narrowly on the initial
26 deterministic feature while ignoring the irrelevant feature and had difficulty learning about this
27 feature when it became relevant. Young children’s broader attention may have allowed them to

1
2
3 more quickly shift to learning about the previously irrelevant feature when it became meaningful
4 for the ongoing task (Blanco & Sloutsky, 2019). Additional work has shown similar beneficial
5 effects of broadly distributing attention on the ability to learn from relevant competing information
6 in both infancy (Best et al., 2013) and in older adulthood (Amer et al., 2016; Weeks & Hasher,
7 2014). Taken together, these findings suggest that younger children are more likely to attend to
8 competing information, rather than focusing narrowly on task-relevant targets, and that this
9 broader attention to competing information may be especially beneficial for learning when the
10 content is relevant to an ongoing task.
11
12
13
14
15
16
17
18
19
20

21 These studies demonstrate that attending to competing contextual information can benefit
22 learning when the information is relevant to task goals. One challenge is how to define learning
23 environments that are context-interactive, in which competing information is meaningful for
24 learning, versus those in which competing information will interfere with task goals and detract
25 from learning. One possibility is that in novel contexts, learning or information-gathering is always
26 part of the broad goal. In such cases, attending to competing information offers an opportunity to
27 build scene semantic content or object category information. Moreover, learning tasks and goals
28 may be clearly defined within formal learning environments (e.g., classrooms) but more difficult
29 to explicitly identify within informal learning contexts (e.g., free play). Thus, the distinction
30 between meaningful context versus unhelpful distraction can depend on the learning environment.
31 Defining the task-relevance of competing information may also depend on the extent to which the
32 learning environment contains redundant features that can support learning. For example, Kloos
33 and Sloutsky (2008) found that categories with only one defining feature were learned most
34 effectively when participants' attention was explicitly directed to this feature, whereas
35 unsupervised learning without any explicit instruction was more effective when multiple features

3 predicted category membership. These results indicate that the structure of the learning task (i.e.,
4 feature redundancy) influenced whether attending to competing information was beneficial for
5 learning.
6
7
8
9

10 As described above, the benefits of ignoring task-irrelevant competing information for
11 learning have been observed in a range of learning tasks and environments, including controlled
12 laboratory tasks, formal classrooms, computer-based lessons and specific learning materials. To
13 date, researchers have relied on a narrower range of tasks to demonstrate that attending to task-
14 relevant competing information can facilitate children's learning, although work with older adults
15 has identified this benefit across multiple paradigms (e.g., Amer et al., 2016; Weeks & Hasher,
16 2014). Future research can investigate whether there are differential impacts of task-relevant and
17 -irrelevant sources of competing information across varying learning environments and tasks. In
18 particular, research can further examine how attending to relevant competing information affects
19 children's learning in both formal learning environments with clearly defined learning goals as
20 well as informal learning environments in which learning goals are less well defined. In the
21 sections below we review available evidence suggesting that developing attention control skills
22 will support more effective learning from relevant competing information in both contexts.

43 ***The Value of Developing Attention Control: Defined Learning Goals***

44
45 Although the research described above has shown that young children may more readily
46 learn from a wider range of both target and competing non-targets (Blanco & Sloutsky, 2019; Deng
47 & Sloutsky, 2015, 2016; Hagen & Hale, 1973; Plebanek & Sloutsky, 2017), additional data suggest
48 that taking advantage of relevant contextual information during target learning requires developing
49 attention control. In a series of studies, Ackerman and colleagues (Ackerman 1986, 1987a, 1987b;
50
51
52
53
54
55
56
57
58
59
60

1
2
3 Ackerman et al., 1989) demonstrated that processing conceptual links between target and non-
4 targets can facilitate learning. In these studies, children and adults completed an oddity task in
5 which they viewed three words and were asked to identify and remember a target word that was
6 conceptually distinct from the remaining words. During easy trials the target word (e.g., nurse)
7 was clearly unique from the non-targets (e.g., rain, snow), whereas during hard trials it was more
8 closely related to the non-targets (e.g., doctor, dentist). At all ages, participants showed enhanced
9 recall for target words encoded during the hard trials. These results suggest that attending to and
10 contrasting the targets and non-targets during the hard trials facilitated encoding, whereas focusing
11 on the conceptually distinct targets during the easy trials was less beneficial for learning
12 (Ackerman 1990; Ackerman et al. 1989). However, the youngest children were less likely to
13 engage in this more difficult contrastive processing during trials in which they could rely on the
14 researcher to identify the unique target word (Ackerman et al., 1989). These results demonstrate
15 that the presence of relevant competing information can benefit children's learning, but young
16 children will not always automatically take advantage of this information.

19
20
21
22
23
24
25
26
27
28
29
30
31
32
33
34
35
36 More recent work similarly demonstrated that the mere presence of relevant competing
37 information does not necessarily benefit children's learning. Remington et al. (2019) examined
38 whether lesson-relevant and -irrelevant classroom decorations differentially affected learning
39 among 7- to 14-year-old typically developing children and those diagnosed with ASD. Children
40 viewed instructional videos in which a teacher appeared in a sparse display without any peripheral
41 images or in a highly decorated display containing background images that were either relevant or
42 irrelevant to ongoing story book lessons. Following the lessons children were tested on their
43 knowledge of the primary lesson topics as well as the background visual information. Children in
44 the ASD group remembered more details about the irrelevant background images, but overall
45

55
56
57
58
59
60

1
2
3 children showed similarly effective learning of the primary story lessons in the context of both
4 relevant and irrelevant background images (Remington et al., 2019). Like Ackerman et al. (1989),
5
6 this research suggests that children do not always automatically process relevant contextual
7
8 information when it is available. Instead, developing attention control skills that affect children's
9
10 selection of relevant vs. irrelevant competing information may affect learning to a greater extent
11
12 than the mere presence of this information. As described above, prior studies have found that the
13
14 extent of children's looking to irrelevant competing information was an important predictor of
15
16 learning outcomes (Erickson et al., 2015; Fisher et al., 2014; Hanley et al., 2017). Consistent with
17
18 this, additional work found that 4-8-year-old children's learning from relevant non-targets during
19
20 a visual search task was predicted by both their attention skills and their looking to the relevant
21
22 information during search (King & Markant, 2020). Children completed an initial encoding task
23
24 and a secondary visual search task that included a subset of objects from encoding as non-targets.
25
26 These objects were labeled "relevant non-targets" since they were related to the initial learning
27
28 task but were not central to the visual search task. Individual differences in developing attention
29
30 skills were assessed based on children's response times to detect the target object during the search
31
32 task. Finally, participants completed a recognition memory task that included all of the objects
33
34 presented during encoding. Children showed overall better memory for objects that appeared as
35
36 relevant non-targets, with the extent of this benefit predicted by children's developing attention
37
38 skills and patterns of looking to the relevant non-targets during search. Children with more
39
40 efficient attention skills showed a larger learning benefit only if they also engaged in increased
41
42 scanning of the relevant non-targets following target detection (King & Markant, 2020). These
43
44 results suggest that children's learning from relevant competing information is an active process
45
46 that requires developing attention skills to support effective search strategies.
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 Overall, several studies have indicated that young children with poorer selective attention
4 skills may learn more from competing non-target stimuli due to their broader attention allocation
5 (Blanco & Sloutsky, 2019; Deng & Sloutsky, 2015, 2016; Hagen & Hale, 1973; Plebanek &
6 Sloutsky, 2017). However, additional work also suggests that children's ability to learn from task-
7 relevant competing information may depend on developing selective attention control (King &
8 Markant, 2020). Blanco and Sloutsky (2019) argued that young children's more distributed
9 attention may allow them to learn from a wider array of information whereas older children and
10 adults may be able to more flexibly control their attention to shift between selective or distributed
11 attention or shift attention across multiple sources of input. Thus, developing control over attention
12 may allow for more effective learning from contextual information as increasing flexibility
13 supports attention to multiple sources of relevant input (Hanania & Smith, 2010) while
14 increasingly efficient selection supports enhanced processing of attended information (Markant &
15 Amso, 2013, 2014).

36 ***The Value of Developing Attention Control: Undefined Learning Goals***

37
38 Developing attention control may also be important for children's learning in informal
39 learning contexts characterized by multiple sources of sensory input but no clearly identified
40 learning goal. Effective learning within these contexts requires learning the structure of the
41 environment while remaining sensitive to relevant information that occurs across multiple inputs.
42 Because complex, dynamic environments contain vast amounts of potentially relevant
43 information, individuals must adopt a search strategy that balances information gathering
44 ("exploration") with effective use of the acquired information ("exploitation"; Gopnik 2020;
45 Nussenbaum & Hartley, 2019). Strategies weighted more towards exploration are aimed at
46
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 gathering a wider range of information, rather than maximizing the value of available information.
4
5 Alternatively, individuals can more narrowly align their search based on the value of available
6
7 information and strategically adjust their search as these values change (Gopnik 2020;
8
9 Nussenbaum & Hartley, 2019).
10

11
12 Researchers studying reinforcement learning, value-based decision making, and causal
13
14 learning have found that young children are more likely to engage in broad exploratory strategies
15
16 rather than responding based on utility or reward outcomes (Gopnik et al., 2015, 2017; Lucas et
17
18 al., 2014; Nussenbaum & Hartley, 2019; Schulz et al., 2019). Younger children show this increased
19
20 exploration despite being able to correctly identify the most valuable reward option (Plate et al.,
21
22 2018). Instead, this broader exploration may reflect young children's less fixed knowledge about
23
24 their environments, prompting them to more readily shift search behaviors. For example, among
25
26 5-, 6-, and 7-year-old children, only the youngest children generated novel problem-solving uses
27
28 for a tool, regardless of whether they were initially informed of the conventional use of the tool
29
30 (German & Defeyter, 2000).
31
32
33
34

35
36 Researchers have argued that visual attention, like exploration, functions as a search
37
38 mechanism aimed at reducing uncertainty about the environment (e.g., Gottlieb 2012, 2018). From
39
40 this perspective, young children's broader distribution of attention may parallel their increased
41
42 exploration and reflect increased uncertainty about their environment. Blanco & Sloutsky (2020)
43
44 examined the relationship between attention and exploration during 4-year-old and adults'
45
46 performance on a value-based decision-making task in which a perceptually salient cue indicated
47
48 either the highest or lowest value choice. Introducing this salient attention cue interfered with
49
50 children's systematic exploration of response options but had little effect on adults' exploitation
51
52 of high-value choices. These results suggest that adults selectively attend to value whereas children
53
54
55
56
57
58
59
60

1
2
3 attend to a broader range of information in support of systematic exploration (Blanco & Sloutsky,
4
5 2020).
6

7
8 Young children's broad distribution of attention may be especially adaptive in undefined
9
10 learning contexts and/or in novel contexts when pre-existing knowledge about the structure of the
11
12 environment is limited. Attending to a wider range of information ensures that children remain
13
14 sensitive to novel information that may become relevant for learning (Blanco & Sloutsky, 2019;
15
16 Rich & Gureckis, 2018). However, the tradeoff of this broad attention distribution is that the
17
18 quality of information processing of attended information is reduced (Blanco & Sloutsky, 2019).
19
20 Thus, as the structure of the environment or task context is learned, attention control may become
21
22 increasingly adaptive to allow for suppression of competing information that is understood to be
23
24 irrelevant while also flexibly shifting attention across relevant inputs. This shift from broad
25
26 distribution of attention to increasing strategic control over attention may parallel observed
27
28 developmental shifts from broad exploration to increasingly strategic exploration. For example,
29
30 compared to children, adults more rapidly adjusted their search strategies to consistently select the
31
32 highest-valued options, despite showing similar levels of initial exploration (Plate et al., 2018).
33
34 These results suggest that adults are better able to strategically control the extent of their
35
36 exploration as they learn the structure of the task. As children acquire knowledge, developing
37
38 attention control may similarly allow them to strategically attend to and learn from multiple
39
40 sources of relevant input while ignoring irrelevant competing information.
41
42
43
44
45
46
47
48
49

50 ***Summary***

51
52
53 Competing information can provide rich input for learning – and should not always be
54
55 ignored. But whether the presence of this competing information will help or hinder learning will
56
57
58
59
60

1
2
3 depend on multiple factors, including the learning goals of the developing child, the learning
4 context that determines the relevance of competing information to ongoing tasks, and children's
5 ability to engage attention control to select relevant information and encode relations across
6 multiple sources of relevant inputs. Future research should be aimed at understanding how these
7 complex interactions across learning contexts and developing attention and memory systems shape
8 children's learning in dynamic environments.

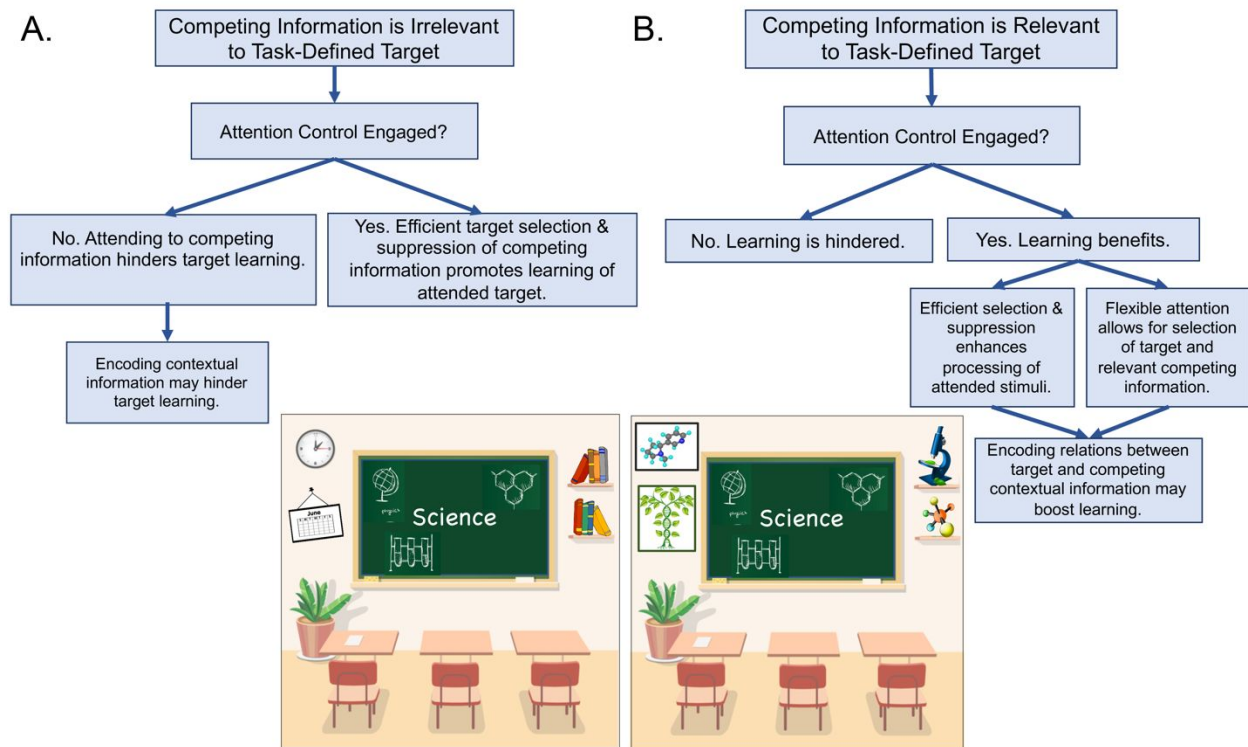

Figure 1. An illustration of the effects of learning context, attention control, and relational encoding on children's learning. (A) In the context of a clearly defined learning task occurring in the context of irrelevant competing information, engaging attention control promotes learning by supporting efficient target selection and suppression of competing distractors. In this case, attending to goal-irrelevant competing information and encoding relations between the target and competing distractors would be detrimental for learning. For example, attending to unrelated or extraneous contextual information during a science lesson can be detrimental to learning. (B) In contrast, when competing information is relevant to an ongoing learning task attending to this information can benefit learning. In this case attention control remains valuable as efficient selection and suppression enhances processing of attended stimuli while flexible attention shifting allows for selection of both the target and relevant contextual information. Encoding relations across the target and competing information may boost learning and provide guidance for subsequent attention orienting. For example, if competing contextual information is related to an ongoing science lesson, attending to this information and encoding the relations between the contextual information and lesson material may benefit learning.
